The Hy⁺ system is a generic visualization tool that supports a novel visual query language called GraphLog. In Hy⁺, visualizations are based on a graphical formalism that allows comprehensible representations of databases, queries, and query answers to be interactively manipulated. This paper describes the design, architecture, and features of Hy⁺ with a number of applications in software engineering and network management.

Visual presentations are widely considered an effective tool to help manage large and complex collections of data. Researchers in scientific visualization (see, for example, McCormick et al.¹) were the first to exploit computer graphics technology to achieve dramatic improvements in the ability of people to understand the data with which they work. The motivation for this exploitation is summarized in the following words from the "Panel Report on Visualization in Scientific Computing," which appeared in the November 1987 issue of *Computer Graphics*:

The gigabit bandwidth of the eye/visual cortex system permits much faster perception of geometric and spatial relationships than any other mode, making the power of supercomputers more accessible. Users from industry, universities, medicine and government are largely unable to comprehend or influence the "fire

hoses" of data produced by contemporary sources such as supercomputers and satellites.

In other diverse domains, such as software engineering, computer network management, and parallel program monitoring, researchers, developers, and users increasingly consider the importance of visual presentation of data. A related idea is to provide data manipulation tools that are themselves visually oriented. The iconic user interfaces common in today's workstations are examples of these tools. Visual query languages for databases² are more ambitious tools for visual data manipulation.

In this paper, we give an overview of the approach to visual display and manipulation of databases that we have been investigating at the University of Toronto for the past few years. We present the design and architecture of the Hy⁺ visualization system and its associated visual query language, GraphLog. Moreover, we describe the use of Hy⁺ and GraphLog in two dif-

ferent application areas: software engineering and network management. In both areas the data have a graph-like structure that can be visualized. Visual queries explore that structure and help the user of Hy⁺ better understand it.

The next section gives a tour of the Hy⁺ system, using a software engineering application as the example. The succeeding section describes the architecture and implementation of the system,

**Hy⁺ provides a user interface
with extensive support for visualizing
structural (or relational) data
as hygraphs.**

particularly of the query processing and graph layout components. Following that section, there is a discussion of further applications to software engineering and, subsequently, a discussion of further applications to network management. We conclude with a discussion for further work.

A tour of Hy⁺

Hy⁺ provides a user interface with extensive support for visualizing structural (or relational) data as *hygraphs*,³ an extension of graphs inspired by Harel's *higraphs*.⁴ The Hy⁺ system supports visualization of the actual *database instances*, not just diagrammatic representations of the database schema. Given the large volume of data that the system must present to the user, it is fundamental to provide the user with two capabilities.

First is the capability to *define* new relationships by using queries. This capability is the traditional way of using database queries: the newly defined relationship either gives a direct answer to a user question, or it provides a new view of the existing data. The derived data can later be presented visually by the system.

The second capability is a way of using queries to decide what data to *show*. The user can selectively restrict the amount of information to be displayed. This *filtering* of relevant information³

is fundamental for conveying manageable volumes of visual information to the user. Selective data visualization can be used to locate relevant data, to restrict visualization to interesting portions of the data (that is, deciding *what* data to present), and to control the level of detail at which the data are presented (that is, choosing *how* to see the data).

To describe queries, Hy⁺ relies on a visual pattern-based notation. The patterns are expressions of the GraphLog query language.^{5,6} Overall, the system supports query visualization (that is, presenting the description of the query using a visual notation), visualization of data constituting the input to the query, and visual presentation of the result.³

We present an example of using GraphLog and its environment Hy⁺ for visualizing the structure of the National Institutes of Health (NIH) public domain C++ class library. The IBM XL C++ compiler was used to extract 13 000 facts from the 35 000 lines of code in the library. In the generated hygraph, the nodes represent classes, functions, and variables. The edges represent relations among them, such as the subclass and friend relationships between classes, the mem relationship between a class and its member functions or variables, the ref relationship between a function and all variables referenced by it, and a calls relationship between functions.

CASE (computer-aided software engineering) tools usually provide a static visualization of the architecture of a software system. Hy⁺ permits a more dynamic approach to the visualization process, allowing different visualizations of the same component to be obtained through different GraphLog queries. In that respect, Hy⁺ cannot only visualize the structure of the class library, but can also explore and better understand that structure.

Any visualization can be queried. Figure 1 contains two examples of queries. The first query is what in GraphLog is called a *filter* query: a GraphLog expression enclosed in a showGraphLog box. It describes a pattern to be matched in the hygraph designated as the database. As can be seen, one of the edges in this pattern is thick, that is, distinguished. This pattern is a visual way of distinguishing edges that the user actually wants to see after the match is found. This particular filter query searches the database for subclasses

Figure 1 Examples of a filter and a define query

Figure 2 Definition and filtering of members

C of class `class('Object')` that redefine some function `F` defined in `class('Object')`. From all objects that match this pattern, only the relation `mem` between the subclass `C` and the inherited function `F` is displayed to the user. Throughout the paper we use the convention that words beginning with an uppercase letter denote variables, whereas words beginning with a lowercase letter denote constants.

The other query in Figure 1 is a *define* query: a `GraphLog` expression in a `defineGraphLog` box. A thick edge here has a different meaning. It represents a relation that is defined every time the pattern is found in the hygraph designated as the database. The define query in Figure 1 defines the relation `uses` between a class `C1` and another class `C2`, whenever `C1` contains a function `F1` that directly or indirectly calls a function `F2`, which is defined in `C2`.

Hygraphs extend graphs by using blobs in addition to edges to represent relationships among nodes. A *blob* in a hygraph represents a relation between a node, called the *container node*, and a set of other nodes, called the *contained nodes*. Blobs are hence generalizations of edges and can be used to cluster related nodes together. Visually they are represented as a rectangular area associated with the container node. The define query of Figure 2 demonstrates how we can change the representation of a relationship from edges to blobs. The blob called `members` clusters the member functions of a class together: a function `F` defined at line `L` is enclosed in the blob associated with `class(C)`, whenever `mem(class(C), function(F,L))`. A blob relation can be treated similarly to an edge relation. The second hygraph in Figure 2 is a filter query that generates a hygraph containing all the `members` blobs and all the `subclass`, `calls`, and `uses` edges that exist in the database.

Figure 3 Hy⁺ architecture overview

System architecture and implementation

Hy⁺ has evolved from the G⁺ Visual Query System presented in Reference 7. The new system is implemented as a frontend, written in Smalltalk, that communicates with other programs to carry on its tasks, including multiple database backends for the actual evaluation of the queries. An overview of the Hy⁺ system architecture is given in the diagram in Figure 3.

Hygraph browsers. Hy⁺ browsers allow users to interact with the hygraph-based visualizations that the system manipulates. They have extensive facilities for interactively editing hygraphs, including copy, cut and paste, panning and zooming, and textual editing of node and edge labels. Icons are automatically selected for nodes according to the functor of the node label (that is, the type of data object represented by the node). Similarly, the colors for edges and blobs are au-

tomatically selected based on the predicate in the label (that is, the relationship represented by the edge or blob).

Within Hy⁺, all blobs associated with one container node are represented by rectangles contained within a rectangular region that has the container node in the topmost left corner. Blob labels are drawn in the interior of the topmost left corner of the rectangle representing the blob. Control over the level of detail displayed is achieved by interactively hiding and showing blob contents. When blob contents are hidden, the incoming and outgoing edges are also hidden (but there are options to present summaries of the information carried by the hidden edges).

Query processing. Query processing in Hy⁺ is performed by translating queries (and data, if necessary) into logic programs suitable for execution by one of two backends: the logic programming language LDL of Microelectronics and Computer Technology Corporation (MCC)⁸ and the experimental deductive language CORAL of the University of Wisconsin.⁹ In this subsection, we give a more precise definition of GraphLog, and we describe how the query processing proceeds within the Hy⁺ system.

In GraphLog, a *term* is one of the following: a constant, a variable, an anonymous variable (as in Prolog), an aggregate function $f \in \{\text{MAX}, \text{MIN}, \text{COUNT}, \text{SUM}, \text{AVG}\}$ applied to a variable, or a functor f applied to a number of terms. An *edge (blob) label* is a *path regular expression* E generated by the following grammar, where $\bar{T}$ is a sequence of terms and p is a predicate:

$$E \leftarrow E|E; E.E; -E; (E); E+; E*; E?; p(\bar{T}); \neg p(\bar{T})$$

Database instances are hygraphs whose nodes are labeled with ground terms and whose edges and blobs are labeled with predicates. Database instances of the object-oriented or relational model can easily be visualized as hygraphs. For example, an edge (blob) labeled $p(\bar{X})$ from a node labeled T_1 to a node (containing a node) labeled T_2 corresponds to tuple $(T_1, T_2, \bar{X})$ of relation p in the relational model. No key is associated with the relation p .

Queries are sets of hygraphs whose nodes are labeled by terms, and each edge (blob) is labeled by

an edge (blob) label. As explained in the previous section, there are two types of queries: *define* and *filter*. In both, the query hygraph represents a pattern; the query evaluator searches the hygraph designated as the database for all occurrences of that pattern. The difference between the two types of queries stems from their interpretation of *distinguished elements*, explained below.

A hygraph pattern in a define query (which is enclosed in a `defineGraphLog` box) must have only one distinguished edge or blob labeled by a positive literal. The meaning of the define query hygraph is to define the predicate in this distinguished literal in terms of the rest of the pattern. The semantics of define queries is given by a translation to stratified Datalog.⁵ Each define hygraph translates to a rule with the label of the distinguished edge or blob in the head and as many literals in the body as there are nondistinguished edges and blobs in the hygraph. Additional rules may be necessary to define the predicates of nondistinguished edges or blobs that are labeled by regular expressions. The generation of these additional rules is based on the structure of the regular expression. An alternative translation is described in Reference 10.

A hygraph pattern in a filter query (which is enclosed in a `showGraphLog` box) may have several distinguished nodes, edges, and blobs. The meaning of a filter query hygraph is: for each instance of the pattern found in the database, retain the database objects that match the distinguished objects in the query. Given a hygraph in a `showGraphLog` box, for each distinguished edge (blob), we generate a set of define queries that *match* the distinguished object; that is, when they are evaluated, they determine all instances of the edge (blob) that exist in the portions of the database that match the hygraph pattern. The query evaluator evaluates each of the define queries in turn. The results are combined, and the answer to the filter query is found.

From a logic programming point of view, a define query corresponds to a conventional set of Horn clauses defining a certain predicate, whereas a filter query can be viewed as a set of Horn clause *bodies* in which certain literals are retained after each match and the rest are discarded. In a way,

Figure 4 Examples with aggregate functions

Adapted from M. P. Consens and M. Z. Hasan, "Supporting Network Management Through Declaratively Specified Data Visualizations," *Proceedings of the IEEE/IFIP Third International Symposium on Integrated Network Management, III*

define queries generate theorems, while filter queries generate proofs. A formal definition of filter queries and filtering logic programs can be found in Reference 3.

GraphLog has the ability to collect multisets of tuples and to compute aggregate functions on them. The aggregate functions supported in GraphLog are the unary operators MAX, MIN, COUNT, SUM, and AVG. They are allowed to appear in the arguments of the distinguished relation of a define query as well as in its incident nodes. As an example of the use of aggregation in GraphLog, consider the two defineGraphLog blobs of Figure 4. The first one defines the relation *quant_uses* between two classes. Relation *quant_uses* is different from relation *uses* of Figure 1; the additional attribute in *quant_uses* defines the degree of coupling between the two classes. Thus, *quant_uses*(C1, C2, COUNT(F2)) is defined between C1 and C2, whenever C1 contains a function F1 such that F1 calls COUNT(F2) functions F2 in class C2. The second pattern defines the relation *avg_usage* to measure the average usage of each class as follows: *avg_usage* is defined between a class C1 and a number AVG(N), where AVG(N) is the average of all numbers N that count the number of calls from functions of class C1 to functions of some other class C2. Note that there is no explicit GROUP-BY list (as in SQL—Structured Query Language). Instead, grouping is done

implicitly over all variables appearing in the distinguished edge or its end points.

GraphLog has higher expressive power than SQL; in particular, it can express, with no need for an explicit recursion construct, queries that involve computing transitive closures or similar graph traversal operations. The language is also capable of expressing first-order aggregation queries, as well as aggregation along path traversals (for example, shortest path queries).¹¹

Data acquisition. The Hy⁺ system relies on other programs (which are part of the Data Acquisition subsystem) to supply the raw data to be visually manipulated within the system. The File Manager subsystem can directly import files containing logical facts (like the ones produced by the XL C++ compiler for the NIH database of the previous section). These files can also be obtained from relational and deductive databases.

External hygraph representation. Graph Exchange Format (GXF) is a specification for a portable external representation for directed graphs and hygraphs.¹² Hy⁺ can read and write graphs in GXF format from and to UNIX** files, and uses optional records or "extensions" of GXF to store all layout and display-related information. Processor programs may use these Hy⁺-specific extensions to manipulate the visual representation of a hygraph, for example, for layout tasks.

Figure 5 Synchronized graphical and textual browsing of source code

Adapted from M. P. Consens and A. O. Mendelzon, "Hy⁺: A Hygraph-based Query and Visualization System," *Proceedings of the 1993 ACM SIGMOD International Conference on Management of Data*

GXF files encode hygraphs in a recursive list structure with a syntax very similar to that of the LISP language. A GXF file is structured into *lists* that contain one keyword and multiple *atoms* (numbers and strings), and may also contain nested sublists. Unparsed comments can also be included. A GXF file consists of one or more top-level GXF lists, at least one of which has the keyword *Graph*, and it contains the encoding of a hygraph. This top-level *Graph* list is decomposed into sublists that represent various parts of the hygraph: its edges, nodes, blobs, etc. These sublists are decomposed further to describe individual edges, nodes, and blobs, and further yet to describe some individual data, such as label, position, and shape. Part of the GXF representation of the graph in Figure 1 follows:

```
; Hygraph fileout (a comment)
(GRAPH (ID "fche@rock.db: Fri Jul 31 12:07:44 EDT 1992" )
  (BOUNDS (RECTANGLE (XY 0 0 ) (XY 1 1 )))
  (NODES (NODE (ID "1" )
    (LABEL "class('Object')" )
    (POINT (XY 0.1 0.8 ))
    (BOUNDS (RECTANGLE (XY 0.1 0.8 )
      (XY 0.11 0.81))))
    = more nodes
  (BLOBS (BLOB
    (FROM "4" ) ; container node
    (TO "1" ) ; contained nodes
    (TO "2" )
    (TO "3" )
    (LABEL "showGraphLog" )
    (BOUNDS (RECTANGLE (XY 0.1 0.1 )
      (XY 0.9 0.5 ))))
    = more blobs
  (EDGES (EDGE
    (FROM "1" ) ; from-node
    (TO "2" ) ; to-node
    (LABEL "mem" ))
    = more edges ))
```

Tool integration. The system has the ability to invoke external programs that, for instance, browse an object being represented by a node in one of the graphs displayed by the system. The Hy⁺ visualizations can be used as overviews to locate information and then invoke third-party browsers to display the contents associated with the relevant objects. An obvious advantage of this approach over a purely navigational one is the ability to use the convenience and expressive power of GraphLog patterns to retrieve the objects of interest, instead of attempting an often impractical brute force search. Of course, this approach is in addition to the use of Hy⁺ to generate as many specifically tailored overviews as needed. Figure 5 has an example of such an integration.¹³ To the right of a specialized hygraph browser there is a Lector**¹⁴ window that displays the source code associated with the object selected in the browser (the code for class('Ident-Dict')). The display synchronization works both ways: when the user changes the page of source code displayed by Lector, the object selected in the Hy⁺ browser adjusts correspondingly. Furthermore, the query evaluation component has been extended to handle a mixture of traditional and textual queries. The latter kind of queries are handled by the PAT** Text Searching Engine.¹⁵

Hygraph layout. When data are imported into Hy⁺ from nongraphical sources, or when answers to queries are computed, it is necessary to compute a *layout* for the resulting hygraphs, that is, to determine how the abstract topology of the hygraph will be embedded into a two-dimensional picture. Unlike many tools that offer a fixed set of predetermined layouts or visualizations, Hy⁺ provides a flexible and interactive layout mechanism that is essential to allow domain experts to easily experiment with a variety of (possibly unanticipated) visual representations and layouts.

To compute hygraph layouts, Hy⁺ uses the graphite utilities developed within our project.¹⁶ The current implementation of graphite consists of several UNIX filters. The graph layout filter reads a GXF description of a hygraph from stdin, internally modifies the position and size information of various hygraph elements in accordance with particular layout criteria, and writes the description of the modified hygraph to stdout. The graphite graph layout filter has also been used to generate three-dimensional graph layouts for a prototype

Figure 6 Mapping the hygraph formalism onto the generic container model

graph browser incorporated into 4Thought,¹⁷ a software development environment.

Layout architecture. To provide more flexible and powerful drawing facilities, we designed every graphite layout algorithm with respect to a generic container model: a container may recursively contain (sub)containers; containers may optionally be linked by directed arcs. The hygraph formalism is mapped onto this model as shown in Figure 6. The figure essentially says that a graph container may contain one or more node containers, each of which contains a label region, icon region, and blobs region containers. Similarly, a blobs region may contain one or more blob containers, each of which contains a nodes region and a label region container. Finally, a nodes region may contain one or more node containers. All containers are treated uniformly by layout algorithms, thereby allowing the same layout algorithm to be used to position the subcontainers of container types.

Basic layout algorithms. The current version of layout filter is capable of producing a drawing us-

ing arbitrary combinations of the following simple parametric layout algorithms (each algorithm supports both two-dimensional and three-dimensional layouts):

1. Cluster: size-based clustering layout—Containers are divided into clusters according to size and shape similarity. Each cluster is laid out independently, and then resulting drawings are combined to form a composite, similar to the technique described in Reference 18.
2. Circle: elliptical layout—Containers are positioned along the perimeter of an ellipse; containers are ordered to reduce (but not necessarily minimize) the number of arc crossings.
3. Grid: grid layout—Containers are positioned at the intersections of an $m \times n$ grid. Containers are placed, one connected component at a time, in top-to-bottom left-to-right order, and are ordered to reduce (but not necessarily to minimize) the number of arc crossings.
4. Hier: hierarchical layout—The algorithm computes a depth-first spanning forest¹⁹ F of the input graph, and places containers by following tree arcs with respect to F , and is similar to several approaches found in the literature.^{20,21}
5. Nop: no layout—The positions of containers are not altered. This method can be used to provide a form of incremental layout capability.
6. Overlap: overlap elimination—Containers are repositioned to eliminate overlaps in a manner similar to the *horizontal shuffle* algorithm,²² except that containers are shuffled along both the x and y axes (and z for three-dimensional layouts).
7. Pack: quadtree-based two-dimensional bin packing—Containers are placed into a small enclosing region by an incremental (and heuristic) quadtree-growing approach.
8. Random: random layout—Containers are positioned randomly without overlaps.
9. Spring: force-based layout—Containers are positioned according to the following analogy to a physical system: containers are treated as charged bodies that repel one another; arcs are treated as springs attached to pairs of containers that pull each member of the pair toward the other. The simulation continues until a low-energy state is reached, resulting

in the final layout; similar approaches have been described in References 23, 24, and 25.

10. Stack: stack layout—Containers are positioned along the axis that results in the most square (cubical) or compact drawing.
11. 1d: one-dimensional layout—Containers are positioned along one of the specified axes.

Each layout algorithm can be controlled by manipulating a number of generic and algorithm-specific parameters. Furthermore, the graphite layout filter can also be used to generate nongeometric fish-eye views of nested graphs^{26,27} that can be used to balance local detail and global context by automatically emphasizing some regions of the layout while simultaneously de-emphasizing others.

Composite hygraph layout. Composite layout is a graph layout technique in which the input graph is partitioned into several subgraphs that are laid out independently (by different layout algorithms) and then composed to produce the final drawing.^{18,28}

The graphite layout filter is capable of performing a composite layout of general graphs at a much finer level of granularity than previous efforts. The filter allows a (possibly unique) algorithm to be associated with each container in the container hierarchy (see Figure 6) induced by a hygraph. If a container is not assigned a layout algorithm, it inherits the algorithm of the parent container. In a composite layout scenario, in addition to the top-level container, a (possibly) unique layout algorithm can be associated with each node, blob, nodes region, and blobs region container by inserting appropriate layout directives into the GXF file.

Software engineering applications

Earlier in this paper, we introduced Hy⁺ and the GraphLog query language by visualizing the structure of a C++ class library and querying that structure during software development to facilitate program understanding. Hy⁺ has been applied to software structures in References 29 and 30 and to debugging distributed applications in Reference 31.

In this section, we give additional examples using the same database as given earlier in the tour of Hy⁺, that is, the NIH C++ library. Once again,

Figure 7 Defining synonyms for functions and displaying some of them

the objects of interest include classes, functions, and variables. Relations between these objects include the subclass relation between two classes, the mem relation between a class and its member functions, the friend relation between two classes or between a class and a function, the relation virtual between a class and its virtual member functions, and the relation pure-virtual between a class and its pure virtual functions (that is, functions that are defined as virtual but with no implementation given for them).

In a language with inheritance, it is not always obvious which version of a function will be invoked by a function call. It is useful for a C++ programmer to know where in the inheritance hierarchy a function is defined. Hy⁺ can group together all "synonyms" of a function and associate the resulting set with the name of the function using blobs. The upper part of Figure 7 demonstrates how. First, the relation fmem is defined to relate a class C with a triple fcl(F,C,L), if class C defines function F at source code line number L (ignoring for simplicity the fact that code comes

from multiple files). Then, if class C2 is a subclass of class C1 (or equal to C1) and both classes define the same function F at some line of their code, the triple fcl(F,C2,L2) is placed inside the blob for the function F. The triple fcl(F,C1,L1) is placed when C1=C2 (note the use of the Kleene closure). Part of the answer to requesting these synonyms appears at the bottom of Figure 7. Note that, for the function at, both implementations are provided inside the class Set, whereas the function deepenVBase is defined once in classes Set and Dictionary and twice in class IdentDict.

Another point of interest for C++ programmers is whether a class contains functions that are pure virtual; that is, their interface is available to subclasses of the class, but no implementation is provided by the class. We call such a class incomplete. Figure 8 contains the definition of incomplete classes: a class C is incomplete if it contains at least one pure virtual function. Also, a class C2 that is a subclass of an incomplete class C1 and does not provide the implementation of the inherited pure virtual function is also an incomplete class.

Figure 8 Identifying classes with incomplete implementation

Figure 9 Inheriting from complete classes

The following two examples use Hy⁺ for finding possible design flaws in the C++ program. Both are taken from Meyers,³² who discusses a number of specific ways to improve C++ programs and designs. The first example involves classes that do not have any virtual functions. This means that none of its member functions can be overridden; all subclasses can add new functionality but cannot modify existing behavior because nonvirtual functions impose a mandatory implementation. This restriction can be considered a form of limited inheritance and, according to Meyers, may be an indication of a design problem. The query in Figure 9 finds such designs: the relation `numOfVirtualFunctions` is defined between every class C and the number of virtual functions that are defined in C. If that number is zero, the class is complete; hence, subclasses may not modify any of the behavior of the class. The filter query in Figure 9 requests to see the part of the

class hierarchy that inherits from complete classes.

In the same spirit is the second example from Meyers. A nonvirtual function has both its interface and its implementation specified by the class in which it appears. According to Meyers,³² redefining such a function in a public subclass is not a good design practice. The query in Figure 10 searches for all classes C1 such that C1 redefines a nonvirtual function defined in some superclass C2 of C1.

The above queries can be seen as constraints imposed upon the structure of the database. A software system satisfies these constraints if and only if the answers to the associated queries are empty. More interestingly, when the system fails to satisfy a constraint, Hy⁺ can be used to display

the violation in a meaningful context so that a person can decide whether the violation is harmful or not.

Technology transfer: The use of GraphLog in 4Thought. The 4Thought prototype¹⁷ is a tool that aims to explore applications of database visualization technology to software engineering. The visual query language GraphLog is a suitable notation for expressing the type of software engineering queries that 4Thought needs to support.

4Thought was initially targeted at programming-in-the-large tasks such as architecture, design, and performance tuning^{29,33} in which the database being visualized contains structural information about the program. Here GraphLog is used as a visual query language to specify graphical views, such as call graphs and inheritance hierarchies, of the program database. We believe that GraphLog is a very intuitive way to define program views since software engineers are used to thinking graphically and commonly employ a wide variety of structural diagrams.

Later, 4Thought was applied to programming-in-the-small tasks such as specification³⁴ in which the database being visualized contains the application data. Here GraphLog is used as a visual specification language to define the computation being performed by the application. We feel that specifications written in GraphLog are much easier to understand than equivalent specifications written in purely textual notations, such as pseudocode or predicate logic.

An exciting recent development has been the evolution of databases to support new versions of SQL that allow recursive queries. This means that commercial databases will soon be able to efficiently execute GraphLog queries, making tools like 4Thought and Hy⁺ useful in application domains such as bills-of-material and airline routes. We believe that writing queries for these recursive domains is much easier in GraphLog than in SQL, and we are investigating customer requirements for new database application development tools that exploit graphical visualization.

Network management applications

Managing a large heterogeneous computer network is a complex task. The proposed network management standards for Internet networks

Figure 10 Redefining an inherited nonvirtual function

based on Transmission Control Protocol/Internet Protocol (TCP/IP) and the International Organization for Standardization (ISO) Open Systems Interconnection (OSI) network management standards are attempts by standards organizations to reduce the complexity involved. They propose a manager-agent paradigm, where a management station receives status data from network devices and assembles them into a global picture of the network, that is used to monitor and control network operation. Appropriately visualizing this global picture as well as others can be a very effective aid in managing the network. In general, three techniques are useful for network management: abstraction, filtering, and visualization.

Abstraction: The complexity of managing networks is reduced by systematically imposing different levels of abstraction onto the network. Doing so allows the functional management to be performed in a structured way. Network objects can be abstracted into higher-level entities based on different criteria set by the network manager, for example, geographical sites broken down into buildings, or administrative responsibilities within the network, e.g., domains. Network objects can also be abstracted according to the ISO OSI protocol layering by distinguishing between two different views of the topology map of the network: the *logical map*, which corresponds to the network layer, and the *physical map*, which corresponds to the data-link and physical layers.

Filtering: The limitation in the size of the presentation media makes it difficult to visualize the status of the entire network. When a problem occurs

Figure 11 Defining and displaying the logical network layer map (part1)

in the network, it would be helpful to see only the relevant areas of the network. It would be nice to be able to specify what we want in a simple and declarative way, filter out the problem area, and visualize it in terms of the topology of the network and at different levels of abstraction.

Visualization: In presenting the data to the human manager, it is widely believed that graphical displays are essential; all commercial network management tools make an attempt to communicate information visually. These visualizations tend to be hardwired into the software, with limited control available to the manager. A flexible system where the what and how of visualization is under user control has significant potential for advancing the state of the art in network management software.

Network management in Hy⁺. In this subsection, we show how we can obtain different views of the network using the querying capabilities provided by the Hy⁺ system. The example network management database contains information about the topology of the network and about its constituents. This information is obtained from MIBs (management information bases³⁵). By executing the queries shown in Figure 11, we obtain the logical network layer map shown in Figure 12. Similar queries can produce the physical topology map.

To handle performance bottlenecks and faults, a network must be monitored continuously. The result of monitoring is reflected in *alerts*. Defining alerts and correlating them requires sophisticated and flexible alert definition facilities. By considering the network as a distributed database and the MIB as the schema of the database, alerts can be defined as declarative GraphLog queries.

Suppose that we monitor the utilization of a server called *samba*. For this purpose, we poll the *tcpInSegs* and *tcpOutSegs* TCP MIB objects of the server. These two variables store the total number of TCP segments flowing in and out of the polled server, as calculated from a defined epoch. The values returned are kept in the database as history traces.

An alert can be generated if the server utilization falls below a certain threshold in a particular period of time, for example, during an expected high-traffic period. If the alert goes off, it indicates a possible problem symptom. The queries in Figure 13 define the alert *alert-serv1-util*. Query *define81* finds out the time (pointed out by the distinguished edge *previous_time*) when the previous poll of *samba* was taken. Query *define82* computes the rate of *tcpInSegs* and *tcpOutSegs* traffic in the latest poll interval during high-traffic time.

Figure 12 Defining and displaying the logical network layer map (part2)

Figure 13 Defining an alert for possible problem symptoms

Query define83 checks whether the rate computed in the previous query falls 80 percent below the expected traffic kept on the `traffic_high_server` edge of samba. If the condition is satisfied, an edge called `problem_area` is created from the node labeled samba to the node labeled with the name of the alert.

Assume that the above alert has gone off, and the problem area is the server samba. The alert may fire for various reasons, among them congestion in gateways between the server and the clients or a hardware fault. Assume that we first hypothesized that the cause of the alert was congestion, but the investigation (see Refer-

ence 36) showed no congestion, although it found that the clients of samba are not generating the expected traffic to the server. Our second hypothesis is that the cause of the alert is a hardware problem. In this case, the map showing physical details like repeaters, bridges, data-link layer protocols, and so on is brought up. Before looking for the physical causes of the problem, we superimpose the currently active TCP links on the portion of the physical map that depends on the alert.

Query define101 of Figure 14 can be interpreted as follows: create an edge called `tcp_link` between the hosts `H` that depend on the alert `alert-serv1-util` and

Figure 14 Defining and showing TCP links

Figure 15 TCP links superimposed on the physical topology map

the server samba, if the IP address found in the `tcpConnRemAddress` of the TCP connection table of `H` matches the address of samba (which is stored in the attribute `attr(address)` of the configuration database). Query `show101` produces, as a result, the visualization in Figure 15 showing the portion of the physical topology map that depends on the alert, together with the previously defined `tcp_link` edges superimposed on the map.

The visualization of TCP links allows us to pinpoint the problem area at the portion of the network beyond `ether4`. The problem could be at the repeater `repeater1` or at the Ethernet segments `ether1` and `ether2`. This belief follows from noticing that no TCP connection originates at `ether1` or `ether2`. The SNMP manager could not access the current TCP objects from that part of the network.

The example shows how, when isolating faults in a network, it is advantageous to view network maps at different abstract levels while proceeding in a structured manner to pinpoint the problem area.

Conclusion

We have described the architecture and some aspects of the implementation of the Hy^+ visualization system and its related software. We are encouraged by the ease with which we were able to apply these ideas to a wide variety of applications, including various aspects of software engineering, network management, and distributed and parallel debugging. Traditional data management tools have not been very successful in tackling these kinds of domains; we believe the unique combination of visualization and deductive database features of Hy^+ and GraphLog give us the edge here.

Work is proceeding to extend Hy^+ in several directions, including dynamic visualizations, temporal queries, three-dimensional diagrams, incremental query and layout, and new emphasis techniques for large visualizations. We hope this work is contributing to achieving David Harel's vision:⁴

We are entirely convinced the future is "visual." We believe that in the next few years many more of our daily technical and scientific chores will be carried out visually, and graphical fa-

cilities will be far better than today's. The languages and approaches we shall be using in doing so will not be merely iconic in nature [...] but inherently diagrammatic in a conceptual way [...]. They will be designed to encourage visual modes of thinking when tackling systems of ever-increasing complexity, and will exploit and extend the use of our own wonderful visual system in many of our intellectual activities.

Acknowledgments

The University of Toronto project leading to the development of the Hy^+ system has had a close relationship with the IBM Centre for Advanced Studies (CAS) since its early days. In 1989, we presented what was then called the G^+ /GraphLog system at a technical vitality seminar at the IBM Toronto Laboratory, hosted by Shahram Javey. Arthur Ryman, a member of the laboratory working on an advanced software development environment called 4Thought,¹⁷ saw the potential of GraphLog as a query and manipulation tool in such an environment, leading to a collaboration within one of the first projects of the fledgling CAS. Soon afterwards, we started interacting with Jacob Slonim, by then the head of CAS, on the possibilities of using the G^+ /GraphLog approach for visualizing various aspects of distributed systems, and this interaction led to the data visualization component of the CORDS project.³⁷

In addition to the support from IBM Canada, parts of the work described here were supported by the Natural Sciences and Engineering Research Council of Canada, the Information Technology Research Centre of the Province of Ontario, and the Institute for Robotics and Intelligent Systems, a network within the Networks of Centres of Excellence Programme of the Federal Government of Canada.

We also thank Sergio Faria, Yanni Jew, Christine Knight, Carlos Mendioroz, Brian Sallans, Toomas Toomsalu, and Annie Yeung for their contributions to the development of Hy^+ .

Portions of this paper have appeared in publications of the following conferences: EDBT 1994,³⁰ IEEE/IFIP ISINM 1993,³⁶ and ACM SIGMOD 1993.³⁸ We thank Springer-Verlag, Elsevier Science Publishers, and the Association for Computing Machinery for their respective permission to reprint those portions.

Accepted for publication April 25, 1994.

Mariano P. Consens *Department of Computer Science, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada (electronic mail: mconsens@uwaterloo.ca).* Dr. Consens is Research Assistant Professor in the Department of Computer Science at the University of Waterloo. His interests are in the theory and practice of database systems and data visualization systems. Specific areas of interest are text databases and applied databases for application domains such as software engineering and network management.

Frank Ch. Elgler *Department of Electrical and Computer Engineering, University of Toronto, 6 King's College Road, Toronto, Ontario M5S 1A4, Canada (electronic mail: fche@db.toronto.edu).* Mr. Elgler is a visiting student at the IBM Centre for Advanced Studies and an undergraduate in the Department of Computer Engineering at the University of Toronto. His interests are in the areas of programming languages, deductive databases, operating systems, and computer networks.

Masum Z. Hasan *Department of Computer Science, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada (electronic mail: zmhasan@db.toronto.edu).* Mr. Hasan is a Ph.D. candidate in the Department of Computer Science at the University of Waterloo. His research interests are in the area of distributed systems, network management, and active temporal databases.

Alberto O. Mendelzon *Department of Computer Science, University of Toronto, 6 King's College Road, Toronto, Ontario M5S 1A4, Canada (electronic mail: mendel@db.toronto.edu).* Dr. Mendelzon is a professor in the Department of Computer Science at the University of Toronto. His interests include the theory, practice, and applications of databases and knowledge bases, and in particular the data visualization and data manipulation interfaces for them.

Emanuel G. Noik *Department of Computer Science, University of Toronto, 6 King's College Road, Toronto, Ontario M5S 1A4, Canada (electronic mail: noik@db.toronto.edu).* Mr. Noik is a Ph.D. candidate in the Department of Computer Science at the University of Toronto. His interests include the design and implementation of user interfaces, human-computer interaction, relational data visualization, graph layout,

three-dimensional user interfaces and virtual reality, and hypermedia systems.

Arthur G. Ryman *IBM Software Solutions Division, Toronto Laboratory, 895 Don Mills Road, North York, Ontario M3C 1W3, Canada (electronic mail: ryman@vnet.ibm.com).* Dr. Ryman is a senior development analyst in the Application Development Technology Centre (ADTC) of the IBM Toronto Software Solutions Laboratory. He is currently leading an advanced development project that is incorporating the GraphLog visual query language into 4Thought, an interactive graphical tool applicable to software engineering and database prototyping.

Dimitra Vista *Department of Computer Science, University of Toronto, 6 King's College Road, Toronto, Ontario M5S 1A4, Canada (electronic mail: vista@db.toronto.edu).* Ms. Vista is a Ph.D. candidate in the Department of Computer Science at the University of Toronto. Her interests are in the area of query processing, query optimization, and incremental query evaluation, especially as they apply to visual query languages and database visualization.
